## Notation

$\boldsymbol{x}$	A vector
$\boldsymbol{X}$	A matrix
$\mathbf{X}$	A Tensor
$\boldsymbol{X}_{ij}$	Element located at row $i$ column $j$ in matrix $\boldsymbol{X}$
*	The convolution operator
o	The Hadamard product
$\sigma$	The sigmoid activation function
$\nabla_{\boldsymbol{x}} f$	Gradient of $f$ with respect to $\boldsymbol{x}$
$f(\boldsymbol{x}; \theta)$	Function $f$ with input $\boldsymbol{x}$ and parameter $\theta$
$\mathcal{U}(a, b)$	Uniform distribution with support $[a, b]$

# 1 Introduction

## 1.1 Related Work

2-dimensional pose estimation can be divided into either being image-based or video-based, where the methods in the latter case use the tempoeral information of the video to perform the pose estimation.

Image-based methods were initially based on the geometry between the joints of the taget image [17, 20, 25]. Following this, were the convolutional-based methods, that used convolutional neural networks [12] to perform the pose estimation [22, 15, 4, 8]. More recent methods use transformers [21] to deliver state-of-the-art results [23, 24].

Early video-based methods used 3-dimensional convolutions to capture the temporal information between neighboring frames [16, 5]. Other methods use LSTM's [9] to capture this temporal information [13, 2]. Like in the case of image-based methods, transformers [21] have recently been introduced to the video-based methods to capture the temporal information and deliver state-of-the-art-results [26].

## 1.2 Problem Definition

## 1.3 Reading Guide

## 2 Deep Learning Theory

The following section covers the most important background theory for the experiments in Section ???. This includes an introduction to various types of neural networks, as well as an introduction to the optimization of such networks.

### 2.1 Feedforward Neural Networks

**Feedforward neural networks** are the most basic type of neural networks. The aim of a feed-forward neural network is to approximate some function  $f^*$ , by defining a mapping  $\mathbf{y} = f(\mathbf{x}; \boldsymbol{\theta})$  and learning the parameters  $\boldsymbol{\theta}$ , that results in the best approximation of  $f^*$ . These models are called **feedforward** because there are no **feedback** connections in which the outputs of the model are fed back into itself. Instead, information flows through the function being evaluated from  $\mathbf{x}$ , through the intermediate computations used to define  $f$ , and finally to the output  $\mathbf{y}$ . Feedforward neural networks generally consists of multiple **layers**, arranged in a chain structure, with each layer being a function of the layer that preceded it [7].

#### 2.1.1 Fully-connected Layers

The most simple type of layer found in a feedforward neural network is the **fully-connected layer**. The fully-connected layer usually consists of some learnable parameter matrix and learnable parameter vector, as well as a **activation function**, which is a non-linear function, that makes it possible for the network to model non-linearity. Three of the most common activation functions are the **Rectified Linear Unit (ReLU)**, **Sigmoid** and **Hyperbolic Tangent (Tanh)** activation functions, defined as

$$\text{ReLU}(x) = \max\{0, x\} \quad (1)$$

$$\text{Sigmoid}(x) = \sigma(x) = \frac{1}{1 + \exp(x)} \quad (2)$$

$$\tanh(x) = \frac{\exp(x) - \exp(-x)}{\exp(x) + \exp(-x)} \quad (3)$$

Given the learnable parameter matrix  $\mathbf{W}$ , learnable parameter vector  $\mathbf{b}$  and activation function  $g$ , the  $i$ 'th fully-connected layer is defined as

$$\mathbf{h}^{(i)} = \begin{cases} g^{(i)} (\mathbf{W}^{(i)\top} \mathbf{h}^{(i-1)} + \mathbf{b}^{(i)}) & \text{if } i > 1 \\ g^{(1)} (\mathbf{W}^{(1)\top} \mathbf{x} + \mathbf{b}^{(1)}) & \text{if } i = 1 \end{cases}. \quad (4)$$

Thus, for a neural network with  $n$  layers, we have the mapping [7]

$$\mathbf{y} = f(\mathbf{x}; \boldsymbol{\theta}) = \mathbf{h}^{(n)}. \quad (5)$$

#### 2.1.2 Convolutional Layer

A **convolutional layer** is a specialized kind of feedforward layer, usually used in analysis of time-series or image data. If a network has at least one convolutional layer, it is called a **Convolutional neural network (CNN)** [7].

The convolutional layer consists of a set of **kernels**, each to be applied to the entire input vector, where each kernel is a learnable parameter matrix  $k \times k$  [18]. Each kernel is applied on the input to produce a **feature map**. The kernels are applied to the input by "sliding" over the input (where the step size is called **stride**). Each  $k \times k$  grid of the input is then used to

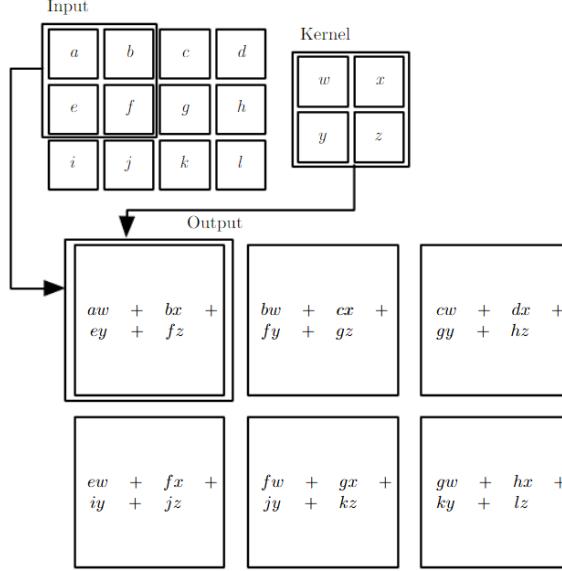

Figure 1: An example of applying a 2d kernel on an input [7].

compute the dot-product between the grid and each kernel, which is then placed in the corresponding feature map of each kernel, as visualized in Figure 1. [1]. To control the dimensions of the output, one might **pad** the sides with a constant value. Commonly, zero is used as the padding-value.

As seen in Figure 1, each kernel produces a linear combination of all pixel values in a neighbourhood defined by the size of the kernel. Thus, unlike a fully-connected layer, a convolutional layer captures the high correlation between a pixel and its neighbours. Further, by limiting the size of the kernel, the network will use much fewer parameters, than if it was replaced by a fully-connected layer [7].

## 2.2 Recurrent Neural Networks

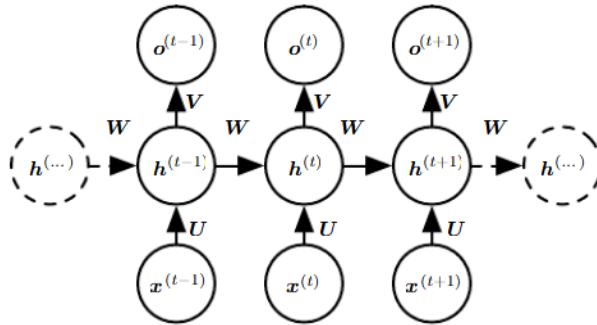

Figure 2: An illustration of an RNN [7].

**Recurrent neural networks (RNNs)** are a family of neural networks for processing sequential data. Figure 2 illustrates the general setup of such a network, which maps an input sequence of  $x$  values to a corresponding sequence of output  $o$  values. Generally, an RNN consists of three parts: (1) the input ( $x^{(i)}$ ), (2) the hidden state ( $h^{(i)}$ ), and (3) the output ( $o^{(i)}$ ). During inference, the model maps each input value to an output value in a sequential matter, where it first maps the first input value, then the second, then the third, and so forth. The network maps each input value to an output value by making use of the hidden state from the preceding step,

where the first hidden state has to be initialized. This kind of RNN is **unidirectional**, as it only considers the data in one sequence-direction. To utilize both directions of the sequence one can use two RNNs, where each RNN processes the data in opposite direction. This type of RNN is called being a **bidirectional RNN (bi-RNN)** [7].

### 2.2.1 Convolutional Long Short-Term Memory

One common recurrent neural network unit is the **convolutional long short-term memory (ConvLSTM)**, which is an adaptation of the standard **long short-term memory (LSTM)** for sequences of images. Both LSTMs work by potentially stacking multiple **cells** together, such that each LSTM cell is taking in outputs of the preceding LSTM cell as its input.

The idea of both LSTM cells is to create paths through time that have derivatives that neither vanish nor explode. This is done by introducing a memory cell  $C_t$ , which accumulates state information over a long duration. This cell is accessed, written and cleared by several controlling gates. The model learns during training, when to access, write and clear this memory cell. By using the memory cell and gates to control the flow of information, the gradient will be trapped in the cell and thus be prevented from vanishing too quickly [7, 19].

The ConvLSTM cell consists of three gates. The first gate is the input gate  $I_t$ , which controls whether or not to accumulate the information of a new input to the cell. This gate is defined as

$$I_t = \sigma(W_{xi} * X_t + W_{hi} * H_{t-1} + W_{ci} \circ C_{t-1} + B_i) \quad (6)$$

where  $X_t$  is the current input image,  $H_{t-1}$  is the hidden state of the previous time step,  $C_{t-1}$  is the cell output of the previous time step, and  $W_{xi}$ ,  $W_{hi}$ ,  $W_{ci}$  and  $B_i$  are learnable parameters

The second gate is the **forget gate** unit  $F_t$  (at time step  $t$ ), which controls whether or not to "forget" the status of the cell output of the previous time step. The forget gate is defined as

$$F_t = \sigma(W_{xf} * X_t + W_{hf} * H_{t-1} + W_{cf} \circ C_{t-1} + B_f) \quad (7)$$

where  $W_{xf}$ ,  $W_{hf}$ ,  $W_{cf}$  and  $B_f$  are learnable parameters.

The last gate is the **output gate** unit  $O_t$ , which controls whether or not the latest cell output will be propagated to the final state  $H_t$ . This cell is defined as

$$O_t = \sigma(W_{xo} * X_t + W_{ho} * H_{t-1} + W_{co} \circ C_t + B_o) \quad (8)$$

where  $W_{xo}$ ,  $W_{ho}$ ,  $W_{co}$  and  $B_o$  are learnable parameters.

By combining the three gates, we get the following definition of the ConvLSTM Cell. Let  $X_1, X_2, \dots, X_t$  be a sequence of input images. Then, at each time step  $t$ , we compute

$$I_t = \sigma(W_{xi} * X_t + W_{hi} * H_{t-1} + W_{ci} \circ C_{t-1} + B_i) \quad (9)$$

$$F_t = \sigma(W_{xf} * X_t + W_{hf} * H_{t-1} + W_{cf} \circ C_{t-1} + B_f) \quad (10)$$

$$C_t = F_t \circ C_{t-1} + I_t \circ \tanh(W_{xc} * X_t + W_{hc} * H_{t-1} + B_c) \quad (11)$$

$$O_t = \sigma(W_{xo} * X_t + W_{ho} * H_{t-1} + W_{co} \circ C_t + B_o) \quad (12)$$

$$H_t = O_t \circ \tanh(C_t) \quad (13)$$

For  $t = 1$ , both  $H_{t-1}$  and  $C_{t-1}$  have to be initialized [19].

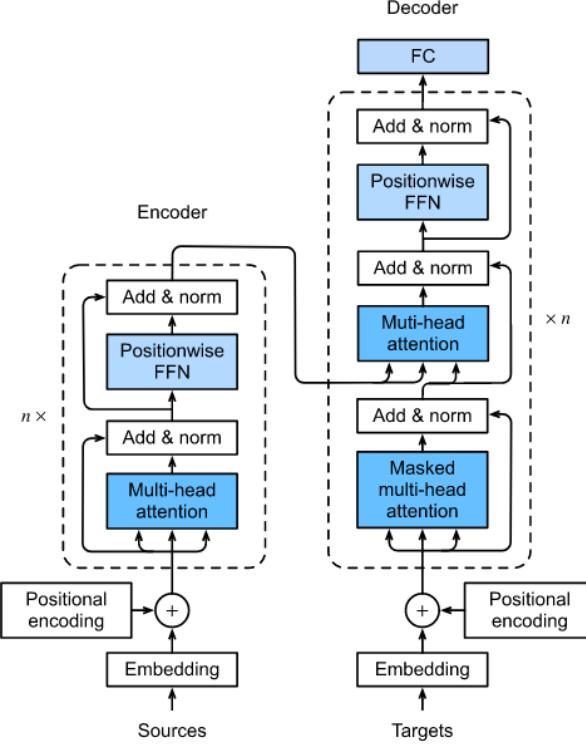

Figure 3: An illustration of the Transformer architecture [27].

## 2.3 Transformer

The sequential nature of RNNs precludes parallelization with training examples, heavily slowing down the training of these models. Another type of model for sequential data is the **Transformer**, which eschews recurrence and instead relies on an **attention** mechanism to draw dependencies between input and output. The Transformer allows for more parallelization and can reach state of the art results [21].

### 2.3.1 Attention

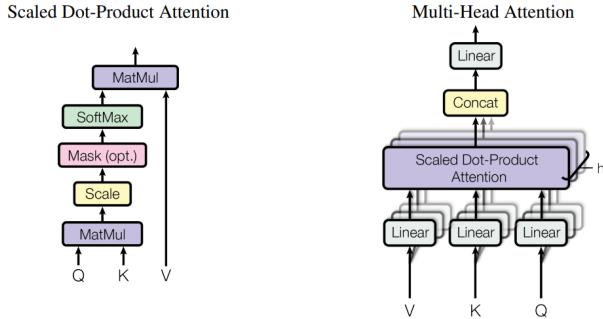

Figure 4: Illustration of (left) the Scaled Dot-Product Attention, and (right) the Multi-Head Attention, which consists of several attention layers running in parallel [21].

An attention function is a function that maps a given query and a given set of key-value pairs to an output. In this function the query, keys, values, and output are all vectors, and the output is a weighted sum of the values, where the weight of each value is computed by a compatibility function of the query with the corresponding key [21]. Figure 4 illustrates the two types of

attention functions used in the Transformer.

**Scaled Dot-Product Attention:** The scaled dot-product attention is the core attention function of the transform. The function takes queries and keys of dimensions  $d_k$  as input, and values of dimension  $d_v$ . In practice, the attention function is computed on a set of queries, keys and values simultaneously, by packing them into matrices  $\mathbf{Q}$ ,  $\mathbf{K}$ , and  $\mathbf{V}$ , respectively. Thus, the scaled dot-product attention is computed as

$$\text{Attention}(\mathbf{Q}, \mathbf{K}, \mathbf{V}) = \text{softmax}\left(\frac{\mathbf{Q}\mathbf{K}^T}{\sqrt{d_k}}\right)\mathbf{V} \quad (14)$$

where the scaling of  $\mathbf{Q}\mathbf{K}^T$  is done to counteract the cases with a large  $d_k$ , which would result in the softmax-function having an extremely small gradient [21].

**Multi-Head Attention:** The **multi-head attention** is the used attention function by the Transformer and is an extention to the scaled dot-product attention. This attention function linearly projects the queries, keys and values  $h$  times with different, learned linear projections to  $d_k$ ,  $d_k$ , and  $d_v$  dimensions, respectively. For each of the projected queries, keys and values, the scaled dot-product attention is applied, yielding  $d_v$ -dimensional output values. These output values are finally concatenated and further projected, resulting in the final values. By using multi-head attention, the model is allowed to jointly attend to information from different representation subspaces at different positions [21].

### 2.3.2 The Architecture

The Transformer follow an encoder-decoder structure, where the encoder maps an input sequence  $\mathbf{x}$  to a sequence of continuous representations  $\mathbf{z}$ . The decoder then uses  $\mathbf{z}$  to generate an output sequence  $\mathbf{y}$ , one element at a time. At each step the model consumes the previously generated output element as additional input when generating the next output [21]. Figure 3 illustrates the overall architecture of the Transformer.

**Encoder:** The encoder consists of  $N$  identical layers, where each layer consists of two sub-layers. The first sub-layer is a multi-head **self-attention** layer, and the second sub-layer is a position-wise fully-connected feedforward network. Around each sub-layer is a **residual connection**, where the the input of the sub-layer is added to the output of the sub-layer. This residual connection is then followed by a round of **layer normalization**. In this self-attention layer the keys, values and queries come from the output of the previous layer in the encoder. Each position in the encoder can attend to all positions in the previous layer of the encoder [21].

**Decoder:** The decoder also consists of  $N$  identical layers. In addition to the two sub-layers in each encoder layer, the decoder also consists of a third sub-layer, which performs multi-head attention over the output of the encoder stack (called **cross-attention** [11]). Also here, is residual connections used around each of the sub-layers, followed by layer normalization. To ensure, that the predictions for position  $i$  only depends on the known outputs at positions less than  $i$ , the self-attention sub-layer in the decoder stack is modified. This self-attention sub-layer, allows each position in the decoder to attend to all positions in the decoder up to and including that position. The self-attention sub-layer is modified by masking out all values in the input of the softmax which correspond to illegal connections [21].

**Feedforward Networks:** Each of the layers in the encoder and decoder contains a fully-connected feedforward layer, consisting of two linear transformations with the ReLU activation-function

applied in between, as described below [21]

$$FFN(\mathbf{x}) = \max(0, \mathbf{x}W_1 + \mathbf{b}_1) W_2 + \mathbf{b}_2. \quad (15)$$

**Positional Encoding:** As the model does not contain any recurrences nor any convolutions, it has to carry some other type of information to know about the relative or absolute position of the elements in the input sequence. This is done by adding **positional encodings** to the input of the encoder and decoder stacks. The positional encoding is a vector of size  $d_{model}$  and is defined as the following

$$\mathbf{PE}_{pos,2i} = \sin\left(\frac{pos}{10000^{\frac{2i}{d_{model}}}}\right) \quad (16)$$

$$\mathbf{PE}_{pos,2i+1} = \cos\left(\frac{pos}{10000^{\frac{2i}{d_{model}}}}\right) \quad (17)$$

$$(18)$$

where  $pos$  is the position and  $i$  is the dimension [21].

## 2.4 General Machine Learning Terminology

The following section covers the general terminology and some algorithms, that will be used through this paper.

**Loss Function:** Training a machine learning model is generally done by minimizing a pre-defined **loss function**, which is used for measuring the error of the model. One common loss function for regression is the **Mean Squared error (MSE)**. Let  $f^*(\mathbf{x})$  be a vector of ground truth observations and  $f(\mathbf{x}; \boldsymbol{\theta})$  be an estimation of  $f^*(\mathbf{x})$ . Then, MSE is defined as

$$MSE = \frac{1}{n} \sum_{i=1}^n \left( f^*(\mathbf{x}^{(i)}) - f(\mathbf{x}^{(i)}; \boldsymbol{\theta}) \right)^2. \quad (19)$$

Thus, MSE measures the average squared difference between the ground truth observations and the estimated observations [10].

**Optimizer:** The minimization of the loss function is usually done by an **optimizer**, which is a type of algorithm, that is typically some type of variation of **gradient descent**. Gradient descent is a process that iteratively updates the parameters of a function by

$$\boldsymbol{\theta} \leftarrow \boldsymbol{\theta} - \eta \nabla_{\boldsymbol{\theta}} L(f(\mathbf{x}^{(i)}; \boldsymbol{\theta}), f^*(\mathbf{x}^{(i)})) \quad (20)$$

where  $\eta$  is called the **learning-rate**, which controls the stepsize of each update, and  $L$  is a loss function such as MSE.

One of the most used optimizers is **ADAM**, which is an optimizer that uses **momentum** and **adaptive learning-rate** to accelerate its learning. Momentum works by accumulating an exponentially decaying moving average of past gradients and continuing to move in their direction, which especially accelerates learning in the face of high curvature, small but consistent gradients, or noisy gradients. Adaptive learning rate is a mechanism for adapting individual learning rates for the model parameters. The idea is as follows; if the partial derivative of the

loss, with respect to a given model parameter, remains the same sign, then the learning rate should increase. If that partial derivate changes sign, then the learning rate should decrease. The algorithm uses a hyperparameter  $\rho$  for controlling the length scale of the moving average. The pseudocode of the algorithm has been illustrated in Algorithm 1. [7].

**Online, mini-batch and batch gradient methods:** Unlike gradient descent, ADAM bases its computations on a **mini-batch** of samples instead of basing it on a single sample. Thus, there are three ways of sampling data for the optimizer. The first way is done by sampling a single sample at each iteration. This class of methods is called **online gradient methods**. The advantage of these methods is, that each iteration is very quick, as we only have to compute the gradient of a single sample, however, the main disadvantage is, that the algorithm uses a lot of iterations. On the other hand we have **batch gradient methods** which uses the average gradient of all of the  $n$  samples of the dataset to compute  $\nabla L(f(\mathbf{x}, \mathbf{y}))$ . By doing so the algorithm only requires one iteration, however, this iteration is much slower than each iteration of the online gradient methods. The last class of methods is **mini-batch gradient methods** which uses the average gradient of  $|B|$  samples of the dataset for computing  $\nabla L(f(\mathbf{x}, \mathbf{y}))$ , where  $B$  is a predefined hyperparameter called the **mini-batch size**. This method lies in between the online gradient methods and batch gradient methods, as it uses fewer iterations than the online gradient methods, however, it uses more iterations than the batch gradient methods. Likewise, each iteration is faster to compute than it is for the batch gradient methods, but slower than it is for the online gradient methods. Further, online gradient methods can lead to a very noisy learning process due to the high variance of the computed gradients of the samples, which can make it more difficult for the optimizer to reach the minimum of the loss function. mini-batch gradient methods and batch gradient methods removes this noise by averaging the computed gradient at each iteration, essentially leading to a quicker learning process [7].

---

#### Algorithm 1 Adam [7]

---

**Require:** Learning rate  $\eta$

**Require:** Exponential decay rates for moment estimates,  $\rho_1$  and  $\rho_2$  in  $[0, 1)$

**Require:** Small constant  $\delta$  used for numerical stabilization

**Require:** Initial parameters  $\theta$

Initialize 1st and 2nd moment variables  $s = \mathbf{0}$ ,  $r = \mathbf{0}$

**while** stopping criterion not met **do**

    Sample a minibatch of  $m$  random observations from the training set  $\{\mathbf{x}^{(1)}, \dots, \mathbf{x}^{(m)}\}$  with corresponding targets  $\mathbf{y}^{(i)}$

    Compute gradient:  $\mathbf{g} \leftarrow \frac{1}{m} \nabla_{\theta} \sum_i L(f(\mathbf{x}^{(i)}; \theta), \mathbf{y}^{(i)})$

$t \leftarrow t + 1$

    Update biased first moment estimate:  $s \leftarrow \rho_1 s + (1 - \rho_1) \mathbf{g}$

    Update biased second moment estimate:  $r \leftarrow \rho_2 r + (1 - \rho_2) \mathbf{g} \odot \mathbf{g}$

    Correct bias in first moment:  $\hat{s} \leftarrow \frac{s}{1 - \rho_1^t}$

    Correct bias in second moment:  $\hat{r} \leftarrow \frac{r}{1 - \rho_2^t}$

    Compute update:  $\Delta\theta = -\eta \frac{\hat{s}}{\sqrt{\hat{r}} + \delta}$

    Apply update:  $\theta = \theta + \Delta\theta$

---

**Layer Normalization:** One problem when optimizing a neural network is, that the gradients with respect to the weights of one layer depends on the outputs of the neurons of the previous previous layer. If these outputs change in a highly correlated way, the model could experience some undesired "covariate shift", which would make the training take longer. One way

to reduce these "covariate shifts" is to make use of **layer normalization**, where the layer normalization statistics over all the hidden units in the same layer  $l$  is computed as the following

$$\mu^{(l)} = \frac{1}{H} \sum_{i=1}^H \mathbf{w}_i^{(l)\top} \mathbf{h}^{(l-1)}, \quad \sigma^{(l)} = \sqrt{\frac{1}{H} \sum_{i=1}^H \left( \mathbf{w}_i^{(l)\top} \mathbf{h}^{(l-1)} - \mu^{(l)} \right)^2} \quad (21)$$

where  $H$  is the amount of hidden units of the  $l$ th layer,  $\mathbf{w}_i^{(l)}$  is the incoming learnable weight vector to the  $i$ th hidden unit of the  $l$ th layer, and  $\mathbf{h}^{(l-1)}$  is the output of the preceding layer. Thus, the summed inputs  $\mathbf{w}_i^{(l)\top} \mathbf{h}^{(l-1)}$  is normalized and rescaled by

$$\bar{a}_i = \frac{\mathbf{w}_i^{(l)\top} \mathbf{h}^{(l-1)} - \mu^{(l)}}{\sigma^{(l)}}. \quad (22)$$

Further, the input to the current layer  $l$  also learns an adaptive bias  $b$  and gain  $g$  for each neuron after the normalization. Thus, the  $i$ th input to layer  $l$  is defined as the following

$$h_i^{(l)} = f \left( \frac{g_i(a_i - \mu^{(l)}) + b_i}{\sigma^{(l)}} \right) \quad (23)$$

where  $f$  is a non-linear activation function [3].

**Evaluation:** We often want to know how well a machine learning model performs on an unseen sample. This is commonly done by splitting the dataset into three non-overlapping subsets to avoid a biased evaluation. The first dataset is the **training** dataset which is used for training the machine learning model. The second dataset is the **validation** dataset which is used during training for evaluating various settings of the the used (hyper)parameters. The last dataset is the **testing** dataset, which is then used for evaluating the final machine learning model.

The evaluation of a machine learning model is done by making use of an **evaluation metric**, which depends on the task of the machine learning model. For pose estimation, the **Percentage of Correct Keypoints (PCK)** is commonly used. This metric measures the ratio of predicted keypoints that are closer to their corresponding ground-truth keypoints than some threshold. Often **PCK@0.2**, **PCK@0.1**, **PCK@0.05** are used, which uses 20%, 10% and 5% of the torso diameter as its threshold, respectively [2].

**Dropout:** A machine learning model is said to be **overfitting** if the loss of the training dataset is decreasing, while the loss of the validation dataset is increasing. One can make use of a group of techniques called **regularization** to avoid the overfitting of the network. One common regularization technique is **dropout**, where each parameter of the machine learning model is randomly disabled with probability  $p$  during training. By doing so the parameters are being trained on the dataset fewer times, leading to less of a probability of the model overfitting.

**Epoch:** Often, the optimizer needs multiple "rounds" of using the whole training data for reaching its minimum. Each of these rounds is called an **epoch**. One can pick the number of epochs to iterate through prior to training a model and just stop the training once the optimizer has used all of its epochs. Another method is to use **early-stopping**, where one keeps track of the loss of the model on the validation-set for each epoch. Once the validation-loss has not decreased for  $n$  consecutive epochs, the training is terminated.

### 3 Models

The following section covers the architectures of the various models that will be used in Section 5 and 6 where we will be performing our experiments.

#### 3.1 Baseline

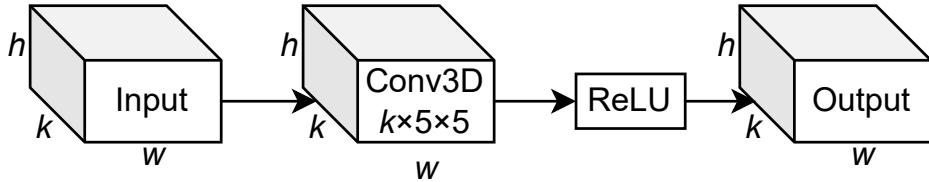

Figure 5: Illustration of the implemented baseline model.

The first model we will be using is a very simple baseline model based on a 3-dimensional convolution. Figure 5 illustrates the architecture of the model.

The model takes a sequence of  $T \in \mathbb{N}$  estimated poses  $\hat{\mathcal{P}} = \{\hat{\mathcal{P}}^t\}_{t=1}^T$  as input, where each estimated pose  $\hat{\mathcal{P}}^t \in \mathbb{R}^{K \times h \times w}$  is represented using heatmaps, such that  $K \in \mathbb{N}$  is the amount of keypoints in each estimated pose,  $h \in \mathbb{N}$  is the height of each heatmap and  $w \in \mathbb{R}$  is the width of each heatmap.

Once the data has been passed to the model, the processing of the data is very simple. As illustrated in Figure 5, the model starts by applying a 3-dimensional convolutional layer to the input data. The convolutional layer consists of  $K$  filters, each with a kernel-size of  $T \times 5 \times 5$ . To ensure the input and output of the convolutional layer has the same shape, we pad the input with zeros.

Once the convolutional layer has processed the data, the ReLU activation-function is applied element-wise to the data, resulting in the final prediction of the model.

#### 3.2 Bidirectional Convolutional LSTM

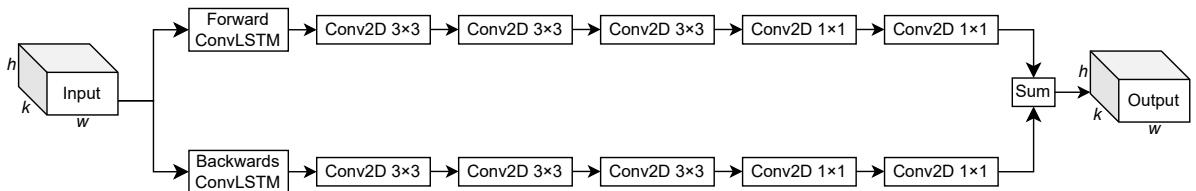

Figure 6: Illustration of the implemented bidirectional convolutional LSTM, where the two sequence orders are summed together.

Our second and third model are based on the LSTM-extension of Unipose-LSTM by Artacho and Savakis [2]. Artacho and Savakis' model was based on a unidirectional convolutional LSTM. However, as we do not require our model to work in real-time, and as we believe a bidirectional convolutional LSTM would be beneficial, our models will be based on a bidirectional convolutional LSTM. The major difference between our second and third model is how they combine the information of the two sequence directions.

Both models take a sequence of  $T \in \mathbb{N}$  estimated poses  $\hat{\mathcal{P}} = \{\hat{\mathbf{P}}^t\}_{t=1}^T$  as input, where each estimated pose  $\hat{\mathbf{P}}^t \in \mathbb{R}^{K \times h \times w}$  is represented as a set of heatmaps, where  $K \in \mathbb{N}$  is the amount of keypoints,  $h \in \mathbb{N}$  is the height of each heatmap and  $w \in \mathbb{N}$  is the width of each heatmap.

### 3.2.1 Summing the Sequence Directions

Figure 6 illustrates the architecture of the second model. The model starts by branching into two separate branches, that processes the estimated poses in opposite sequence order. Each branch processes the estimated poses one frame at a time. This is done by first applying a convolutional LSTM to the input frame at time step  $t \in \mathbb{R}$ , using the preceding output of the convolutional LSTM as the hidden state. Each convolutional LSTM is followed by five 2-dimensional convolutional layers, each applying 128 filters, except for the last convolutional layer of each branch, which applies  $K$  filters. The first three convolutional layers use a kernel size of  $3 \times 3$ , whereas the following two convolutional layers use a kernel size of  $1 \times 1$ . The outputs of the two branches are then summed together element-wise.

All convolutional layers use a stride of one and zero-padding on the input, such that the output of each convolutional layer has the same dimensions as the input to the convolutional layer.

### 3.2.2 Concatenating the Sequence Directions

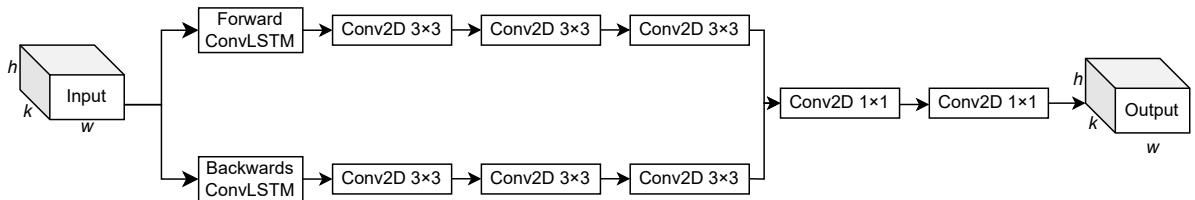

Figure 7: Illustration of the implemented bidirectional convolutional LSTM, where the two sequence orders are concatenated together and processed by two convolutional layers.

Looking at our second model, we see one major problem with the architecture behind it: the model does not have any option of prioritizing one processing order over the other, as the two branches are just summed together. Our third model aims at solving this problem.

Figure 7 illustrates the architecture of our third model. This model is very similar to the previous model. It also starts off by branching into two separate branches, that processes the estimated poses in opposite sequence orders, where each branch processes the estimated poses one frame at a time. Similarly to the previous model, this model also starts off by applying a convolutional LSTM to the input frame, by using the preceding output of the convolutional LSTM as the hidden state. Further, each convolutional LSTM is also followed by three 2-dimensional convolutional layers, each applying 128 filters with a kernel size of  $3 \times 3$ .

Different from the previous model, this model concatenates the output of each branch to form a  $256 \times h \times w$  tensor, which is then processed by two  $1 \times 1$  2-dimensional convolutional layers with 128 and  $K$  filters, respectively.

Similarly to the second model, all convolutional layers also use a stride of one and zero-padding on the input, such that the output of each convolutional layer has the same dimensions as the input to the convolutional layer.

### 3.3 DeciWatch

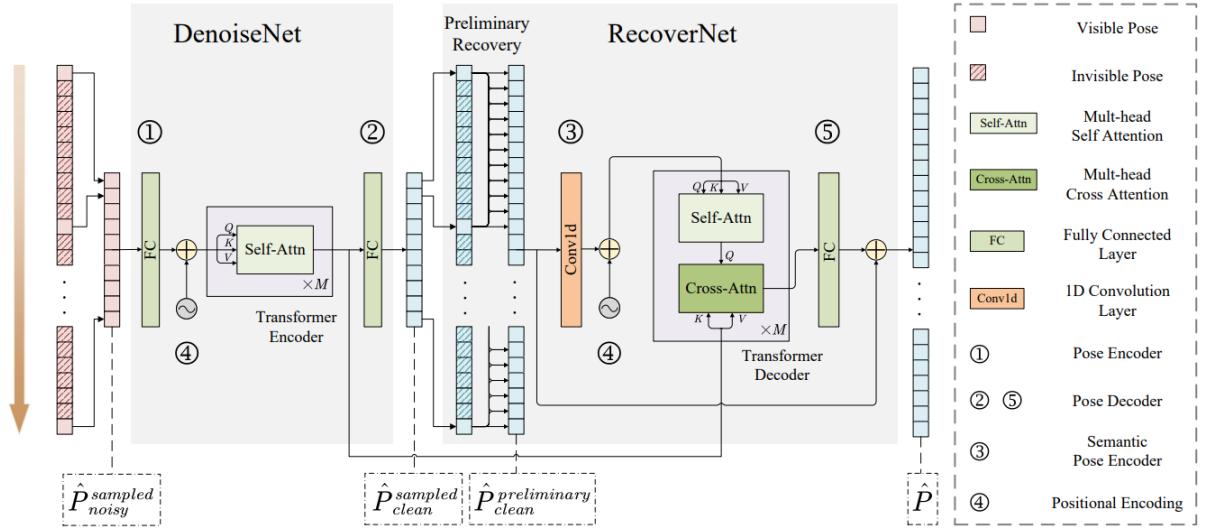

Figure 8: Illustration of the DeciWatch [26]

The last model we implement is a transformer-based model named *DeciWatch*, introduced by Zeng *Et al.*, which is illustrated in Figure 8. The model works by only processing some of the input-frames. It consists of two parts: the *DenoiseNet* and the *RecoverNet*. The aim of DenoiseNet is to denoise the estimated poses given as input to the model, whereas the aim of RecoverNet is to recover the poses of the missing frames. The following description of the model is based on an interpolation of the official paper behind DeciWatch [26].

More specifically, the model takes a sequences of  $T \in \mathbb{N}$  estimated poses  $\hat{\mathcal{P}} = \{\hat{\mathcal{P}}^t\}_{t=1}^T$  as input, where  $\hat{\mathcal{P}}^t$  is represented by 2-dimensional keypoint position. Due to redundancy in consecutive frames and continuity of human poses, the model starts by sampling every  $n$ th frame to select sparse poses  $\hat{\mathcal{P}}_{noisy}^{sampled} \in \mathbb{R}^{\frac{T}{n} \times (2K)}$ , where  $K \in \mathbb{N}$  is the number of keypoints. These sampled poses are then passed to DenoiseNet.

The goal of DenoiseNet is to denoise the sparse poses, that were estimated by a single-frame pose estimator. The denoise process can be formulated as

$$\hat{\mathcal{F}}_{clean}^{sampled} = \text{TransformerEncoder} \left( \hat{\mathcal{P}}_{noisy}^{sampled} \mathbf{W}_{DE} + \mathbf{E}_{pos} \right). \quad (24)$$

That is,  $\hat{\mathcal{P}}_{noisy}^{sampled}$  is first encoded through a linear projection matrix  $\mathbf{W}_{DE} \in \mathbb{R}^{2K \times C}$  and summed with a positional embedding  $\mathbf{E}_{pos} \in \mathbb{R}^{\frac{T}{n} \times C}$ . This is then passed to a transformer-encoder consisting of  $M \in \mathbb{N}$  multi-head Self-Attention blocks, resulting in the noisy poses being embedded into a clean feature  $\hat{\mathcal{F}}_{clean}^{sampled} \in \mathbb{R}^{\frac{T}{n} \times C}$ , where  $C \in \mathbb{N}$  is the embedding dimensions. Lastly, another linear projection matrix  $\mathbf{W}_{DD} \in \mathbb{R}^{C \times 2K}$  is used to obtain the denoised sparse poses

$$\hat{\mathcal{P}}_{clean}^{sampled} = \hat{\mathcal{F}}_{clean}^{sampled} \mathbf{W}_{DD}. \quad (25)$$

After the sparse poses has been denoised as  $\hat{\mathcal{P}}_{clean}^{sampled} \in \mathbb{R}^{\frac{T}{n} \times 2K}$ , the data is passed to the RecoverNet, whose goal is to recover the absent poses. First, a linear transformation  $\mathbf{W}_{PR} \in \mathbb{R}^{T \times \frac{T}{n}}$  is applied to perform preliminary sequence recovery to get  $\hat{\mathcal{P}}_{clean}^{preliminary} \in \mathbb{R}^{T \times 2K}$  by

$$\hat{\mathcal{P}}_{clean}^{preliminary} = \mathbf{W}_{PR} \hat{\mathcal{P}}_{clean}^{sampled}. \quad (26)$$

To improve the recovery of the absent poses a transformer-decoder and positional embedding is used together with a 1D convolutional layer to bring temporal semantics into pose encoding to encode the neighboring  $D \in \mathbb{R}$  frames' poses into pose tokens. Thus, RecoverNet, and the final prediction of DeciWatch, can be summarized by

$$\hat{\mathbf{P}} = \text{TransformerDecoder} \left( \text{Conv1d} \left( \hat{\mathbf{P}}_{\text{clean}}^{\text{preliminary}} \right) + \mathbf{E}_{\text{pos}}, \hat{\mathbf{F}}_{\text{clean}}^{\text{sampled}} \right) \mathbf{W}_{RD} + \hat{\mathbf{P}}_{\text{clean}}^{\text{preliminary}} \quad (27)$$

where  $\mathbf{W}_{RD} \in \mathbb{R}^{C \times 2K}$  is another linear transformation layer. Further, as illustrated by Figure 8, key information is drawn in the the Cross-Attention block by leveraging the denoised features  $\hat{\mathbf{F}}_{\text{clean}}^{\text{sampled}}$ .

To avoid overfitting, dropout is applied to the input of each sub-layer and sums of the embeddings of the transformer-encoder and transformer-decoder, as well as to the positional encodings.

**SKRIV OM HYPERPARAMETER-VALG VED DECIWATCH!!!!!!!!!!!!!!**

### 3.4 Mask R-CNN for Human Pose Estimation

The last model we will be using is the *Mask R-CNN for human pose estimation* as introduced by He *Et al.* in 2017 [8]. Unlike the previously described model, we will not be implementing this model, but instead use an already implemented and trained model on the ClimbAlong dataset, which has been provided by ClimbAlong A/S. As we will not be implementing this model, we will here not go into the details of how the model works, but instead just give a brief overview of the model.

The model takes a single rgb-image with height  $h_{in} \in \mathbb{N}$  and width  $w_{in} \in \mathbb{N}$  as input and returns  $K \in \mathbb{N}$  heatmaps of height  $h_{out} \in \mathbb{N}$  and width  $w_{out} \in \mathbb{N}$  such that each heatmap corresponds to a single keypoint where the position of the element with the greatest value corresponds is the location of the predicted keypoint. The Mask R-CNN by ClimbAlong A/S uses  $h_{out} = w_{out} = 255$  and  $K = 25$ .

Each heatmap corresponds to the predicted bounding-box of the person that the keypoints corresponds to. Further, this bounding-box has been resized such that it is squared, discarding the aspect ratio of the original bounding-box.

## 4 Dataset

To perform the pose estimation in Section ??, we need some data on which to train, validate and test our models. The following section describes the datasets that will be used.

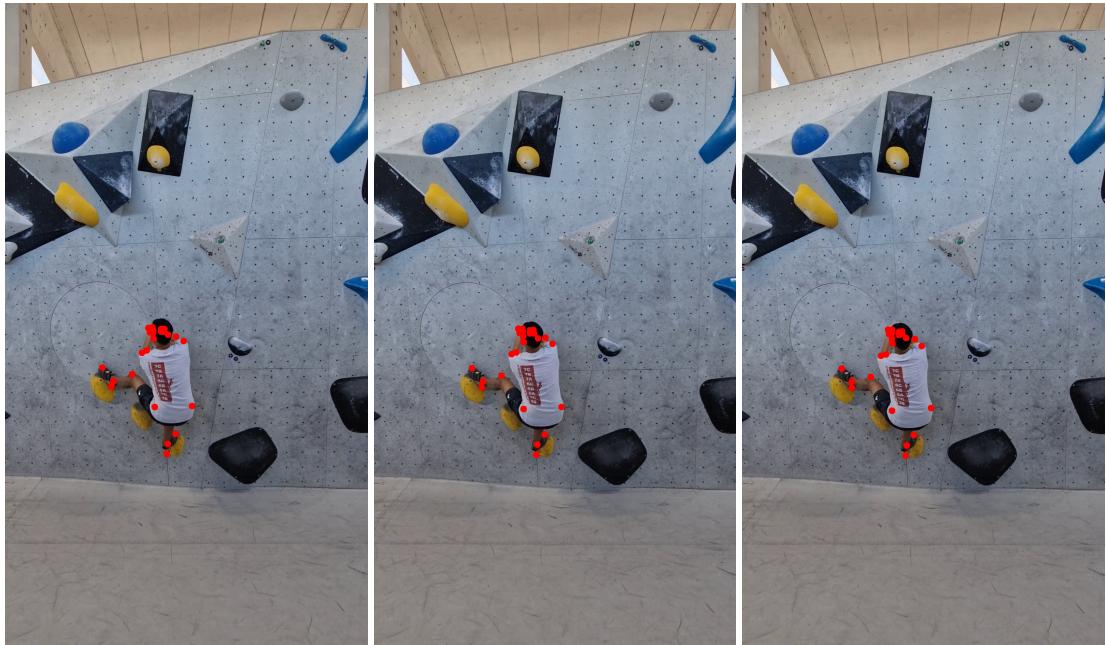

Keypoint label	ClimbAlong	BRACE	Penn Action
Head	No	No	Yes
Nose	Yes	Yes	No
Left ear	Yes	Yes	No
Right ear	Yes	Yes	No
Left eye	No	Yes	No
Right eye	No	Yes	No
Left shoulder	Yes	Yes	Yes
Right shoulder	Yes	Yes	Yes
Left elbow	Yes	Yes	Yes
Right elbow	Yes	Yes	Yes
Left wrist	Yes	Yes	Yes
Right wrist	Yes	Yes	Yes
Left pinky	Yes	No	No
Right pinky	Yes	No	No
Left index	Yes	No	No
Right index	Yes	No	No
Left thumb	Yes	No	No

Right ankle	Yes	Yes	Yes
Left heel	Yes	No	No
Right heel	Yes	No	No
Left toes	Yes	No	No
Right toes	Yes	No	No

Table 1: Overview of the annotated keypoints of the three used datasets

### 4.1 The ClimbAlong Dataset

As the aim of our models is to perform well on climbers, we will be using some annotated data of climbers. For this, ClimbAlong ApS has developed a dataset that we will be using. The dataset consists of videos of various climbers on bouldering walls, where each video contains just a single climber. Figure 9 and 10 illustrates two windows of five consecutive frames of a single video from the ClimbAlong dataset. As shown in the figures, the videos in the dataset contains both static positions, where the climber holds a position for a while, as well as quick movements.

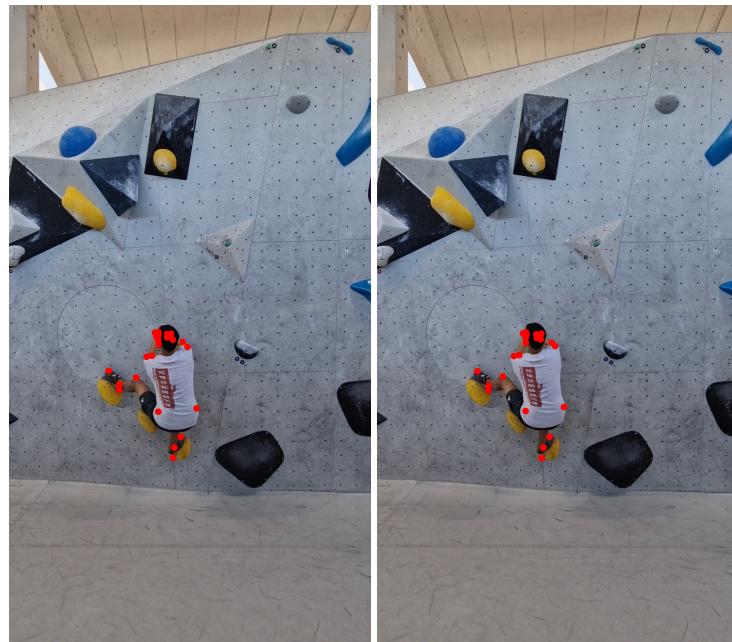

The dataset consists of 29 fully annotated videos and a total of 9,535 fully annotated frames, where each annotation consists of 25 keypoints. Table 1 gives an overview of which keypoints are annotated in the dataset. Each video is filmed in portrait mode with a resolution of

(a) Frame 17

(b) Frame 18

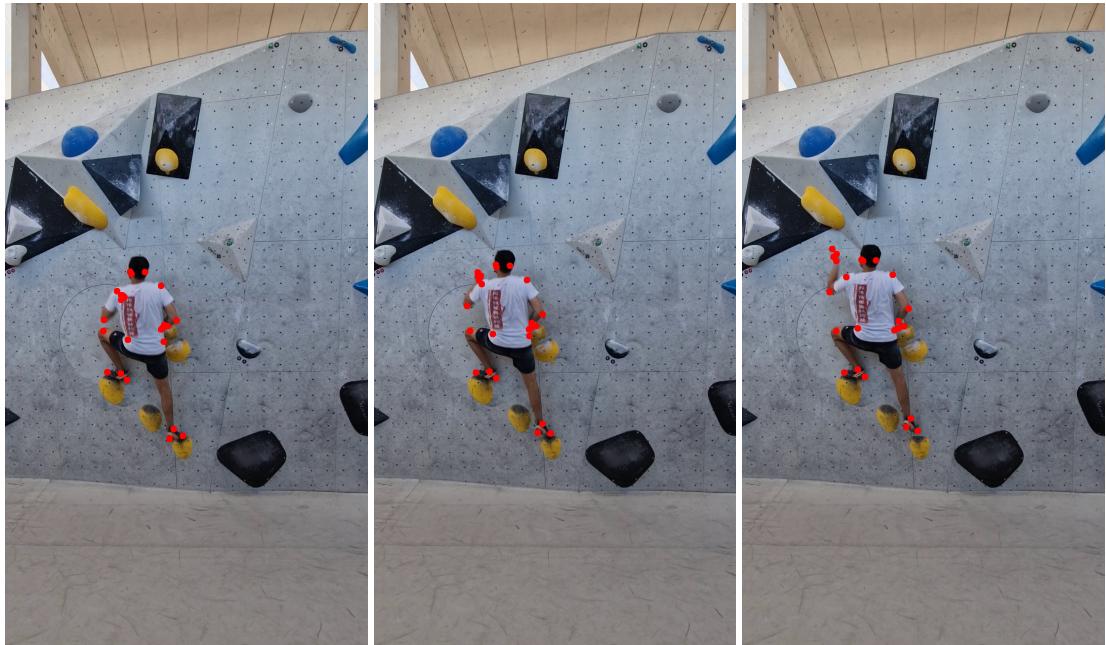

(c) Frame 19

(d) Frame 20

(e) Frame 21

Figure 9: Example of five consecutive frames of a video from the ClimbAlong dataset with the corresponding groundtruth keypoints, where the actor holds his position for a while.

(b) Frame 32

(c) Frame 33

(d) Frame 34

(e) Frame 35

Figure 10: Example of five consecutive frames of a video from the ClimbAlong dataset with the corresponding groundtruth keypoints, where the actor performs a quick movement.

$1080 \times 1920$  and 30 frames per second.

## 4.2 The BRACE Dataset

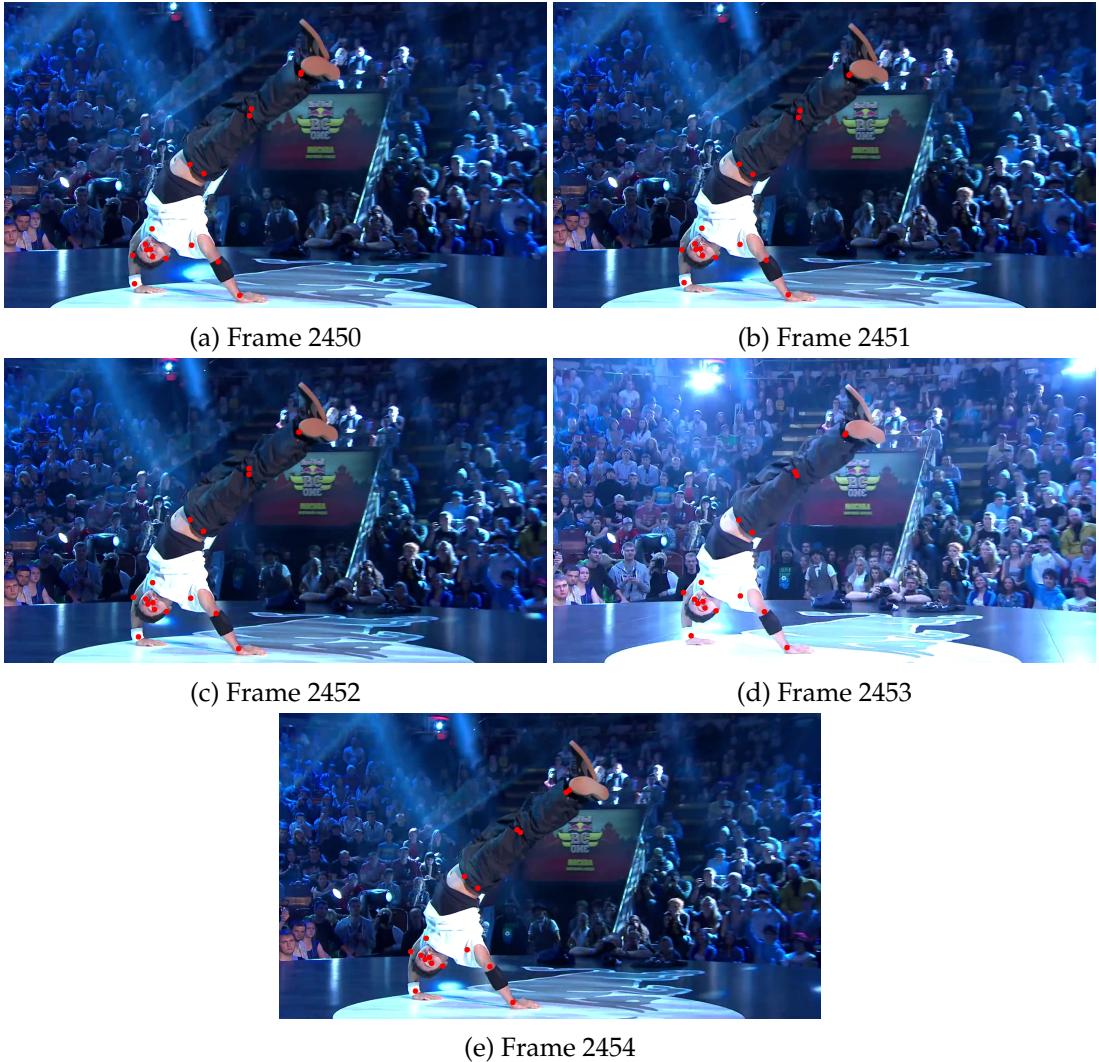

Figure 11: Example of five consecutive frames of a video from the BRACE dataset with the corresponding groundtruth keypoints, where the actor holds his position for a while.

The second dataset we will be using is the *BRACE* dataset [14]. This dataset consists of 1,352 video sequences and a total of 334,538 frames with keypoints annotations of breakdancers. The frames of the video sequences have a resolution of  $1920 \times 1080$  [14].

We chose to use this dataset as breakdancers tend to swap between static and quick poses, as well as containing some acrobatic poses, similarly to the ones seen in the ClimbAlong dataset. Generally, the movements of the BRACE dataset are quicker than the movements of the ClimbAlong dataset. The static poses of the BRACE dataset tend to occur less frequently than the static poses of the the ClimbAlong dataset, as well as the quick movements tend to be quicker than the quick movements of the ClimbAlong dataset. However, as both the actors of both datasets swap between static and quick poses, as well as both datasets containing acrobatic poses, we found the BRACE dataset relevant for our experiments in Section ???. Figure 11 and 12 contains two consecutive sequences, each of five frames, that illustrates these two cases.

Figure 12: Example of five consecutive frames of a video from the BRACE dataset with the corresponding groundtruth keypoints, where the actor performs a quick movement.

baseball_pitch	baseball_swing	bench_press

jumping_jacks	jump_rope	pull_ups
push_ups	sit_ups	squats
strumming_guitar	tennis_forehand	tennis.Serve

Table 2: The original 15 action-types in the Penn Action dataset.

The frames of the video sequences have been annotated by initially using state-of-the-art human pose estimators to extract automatic poses. This was then followed by manually annotating bad keypoints, corresponding to difficult poses, as well as pose outliers. Finally, the automatic and manual annotations were merged by using interpolating. Each frame-annotation consists of 17 keypoints, following the COCO-format, as illustrated in Table 1 [14].

### 4.3 The Penn Action Dataset

The final dataset we will be using is the *Penn Action* dataset [28]. This dataset consists of 2,326 video sequences of 15 different action-types. Table 2 lists these 15 action-types [28].

Each sequence has been manually annotated with human joint annotation, consisting of 13 joints as well as a corresponding binary visibility-flag for each joint. The frames have a resolution within the size of  $640 \times 480$  [28].

Unlike the BRACE dataset, most of the poses in the Penn Action dataset are not very unusual and thus are not very relevant for the poses of climbers. For that reason, we have decided to focus on the action-types that may contain more unusual poses. Thus, we only keep the sequences that have `baseball_pitch`, `bench_press` or `sit_ups` as their corresponding action-type [28]. Further, the movements of the Penn Action dataset tend to be of a more similar pace to the ClimbAlong dataset than the BRACE dataset, making the Penn Action dataset relevant for our task.

In total, we use 307 video sequences from the Penn Action dataset, consisting of a total of 26,036 frames. Figure 13 illustrates five consecutive frames with its groundtruth annotations for one of these video sequences.

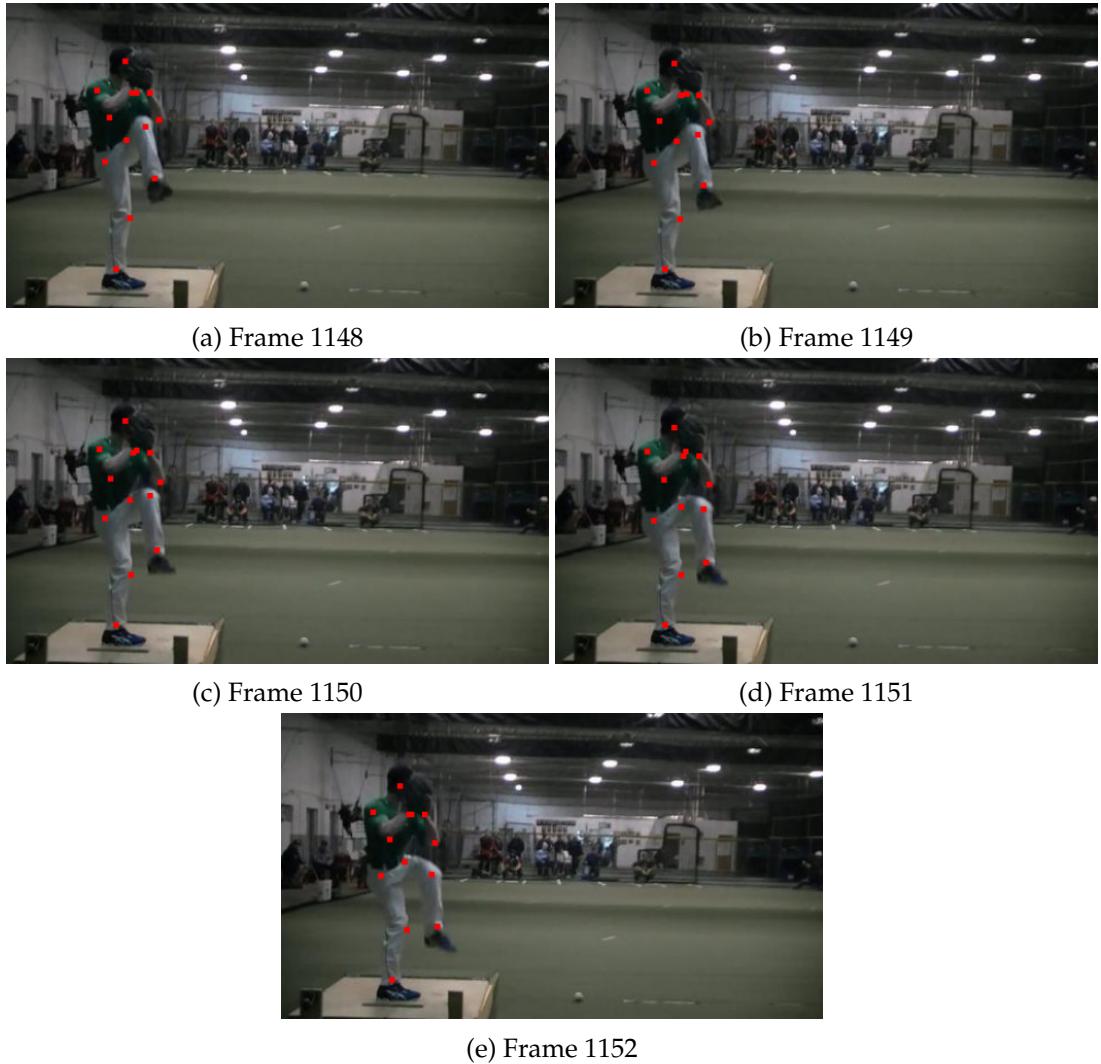

Figure 13: Example of five consecutive frames of a video from the Penn Action dataset with the corresponding groundtruth keypoints.

## 5 Pretraining

As we expect our models to require more data than what is in the ClimbAlong dataset to reach their optimal performance, we have decided to pretrain our models on the BRACE and Penn Action datasets, followed by finetuning them on the ClimbAlong dataset. By doing so we expect our models to yield better results than if we were only using the ClimbAlong dataset, as the pretraining data will be used for adjusting the randomly initialized weights, whereas the finetuning-data will just be used for specializing the model in performing well on the ClimbAlong dataset. The following section describes the pretraining stage, including the data preprocessing, the used configuration details, as well as the obtained results.

In the pretraining stage we will not be using the already developed pose-estimator, but instead only use our temporal-inclusive models by adding noise to the data such that it simulates the output of the already developed pose-estimator on the ClimbAlong dataset. We do this, as the images of pretraining data is very different from the ClimbAlong data, making us believe that the already developed pose-estimator will yield some very inaccurate results, as well as some predictions that will be very different from the predictions of the model on the ClimbAlong dataset.

### 5.1 Data Preprocessing

As our models take a sequence of estimated poses as input, we will not be using the images of the frames, hence why we discard the images of all frames from BRACE and Penn Action, such that we only keep the annotated poses. We further preprocess these annotations, such that they simulate the output of the already developed pose-estimator as closely as possible.

We start by extracting the bounding-box of the annotated pose in each frame by using the annotated keypoints. Further, we expand each side by 10%, such that no keypoint lies on any of the boundaries of the bounding-box. This is followed by discarding everything outside the bounding-box and rescale the bounding-box to have a sidelength of 56, such that it has the same size as the output of the already developed pose-estimator.

Next, we transform each frame into twenty five heatmaps. This is done by creating twenty five  $56 \times 56$  zero-matrices for each frame, such that each zero-matrix represents a single keypoint of a single frame. Further, for each keypoint we insert a fixed value  $c = 255$  at the position of the keypoint in its corresponding zero-matrix and apply a Gaussian filter with mean  $\mu_{out} = 0$  and standard deviation  $\sigma_{out} = 1$  to smear out each heatmap. For missing keypoints, we do not place the value  $c$  in the corresponding heatmap, making the heatmap consist of only zeros. Further, as Penn Action is the only dataset with the position of the head annotated, as well as the only dataset missing a annotation for the nose, we treat the head-annotation of Penn Action as if it was a nose-annotation, as the position of the two annotations would be very close to each other.

The heatmaps that we produce by following the above description will be used as the groundtruth data. However, as we will be pretraining our models detached from the already developed pose-estimator, we will also need some data as input. We acquire this data by adding some noise to the data, such that they become similar to the output of the already developed pose-estimator, essentially simulating the output of the already developed pose-estimator. The noise is introduced by randomly shifting each keypoint of each sample and by smearing our each keypoint of each sample by using a Gaussian filter with mean  $\mu_{in} = 1$  and some standard deviation  $\sigma_{in} \in \mathbb{R}_{>0}$ . For the shift-value we use  $3k$ , where the **shifting-scalar**  $k \in \mathbb{R}_{>0}$  is some fixed positive number. We clip the position of the shifted keypoints between 0 and 55, such

that they cannot be outside of their corresponding heatmap.

## 5.2 Training Details

### 5.2.1 Data Configuration

For the data we use a window-size of  $s = 5$  frames, as Artacho *et al.* found this to be the optimal number of frames to use [2], making our dataset consist of 345,120 windows. Further, we randomly split our dataset into a training, validation and test set, consisting of 60%, 20% and 20% of the data, respectively, without any overlapping or repeating windows among each other. Lastly, to help the models learn the patterns of the data, we shuffle the three subsets, such that the order of which the data is given to the models does not influence the learning.

As the datasets for the pretraining stage are missing some keypoints of the ClimbAlong dataset, we have to cancel out the training of these missing keypoints, as this would otherwise result in the models learning to never predict the presence of these keypoints. There are multiple ways to do this. We handled it during training by setting the groundtruth heatmaps of the missing keypoints equal to the corresponding predicted heatmaps, making the loss of these missing heatmaps be zero and thus the weights of the model of these heatmaps would not be adjusted.

### 5.2.2 Experiments

For each of the four models we run three different experiments. In experiment 1 we uniformly at random sample the standard deviation used by the Gaussian filter at the input data  $\sigma_{in}$  from the set  $\{1, 1.5, 2, 2.5, 3\}$ . We do this, as the output heatmaps of the already developed pose-estimator does not use a fixed standard deviation, making the data a better representation of the pose-estimator output.

As we find it interesting how big of a difference the randomness experiment 1 makes, we fix this standard deviation in experiment 2, such that we have  $\sigma_{in} = 1$ , thus, essentially, the models only have to learn to translate the input heatmaps.

Finally, with 30 frames per second and a window-size of  $s = 5$ , we suspect that the models might be given too little context to actually be able to effectively smooth out the input data. We could fix this by increasing the window-size, however, we instead chose to make the models work at a lower frame rate, as the increased window-size would also increase the memory usage. Thus, for experiment 3 we still use a window-size of 5, however, with half the frame rate. For this experiment we also sample  $\sigma_{in}$  from the set  $\{1, 1.5, 2, 2.5, 3\}$ .

As we find it difficult to set the optimal value of the shifting-scalar  $k$ , such that the data becomes as close as possible to the finetuning data, we run each experiment twice for each model. In the first run we use a shifting-scalar of  $s = 1$ , whereas for the second run we increase the value of the shifting-scalar to  $s = 2$ , making the data a lot more noisy.

### 5.2.3 Training Configuration

For optimizing the weights of the models, we use the ADAM optimizer with a batch size of 16, an initial learning rate of  $10^{-3}$  and the MSE loss-function. During training we keep track of the lowest reached validation loss of an epoch. If this lowest validation loss has not been beaten for five consecutive epochs, we reduce the learning rate by a factor of 0.1. Further, if the lowest validation loss has not been beaten for ten consecutive epochs, we terminate the training of the corresponding model. In case this never happens, we terminate the training of

the corresponding model once it has been trained for fifty epochs.

To reduce the likelihood of vanishing or exploding gradients, we initialize the weights of all models by sampling from the Glorot uniform distribution, defined by

$$\mathcal{U}\left(-\frac{\sqrt{6}}{\sqrt{n_j + n_{j+1}}}, \frac{\sqrt{6}}{\sqrt{n_j + n_{j+1}}}\right), \quad (28)$$

where  $n_j$  is the size of the previous layer and  $n_{j+1}$  is the size of the layer which is having its weights initialized [6].

### 5.3 Training and Validation Results

We have in Figure 14 visualized the evolution of the training loss, validation loss and validation PCK@0.2 accuracy for our 24 models. Each model is delt two numbers seperated by a dot such that it follows a  $x.y$ -format (for instance, '2.3'), indicating what type of shifing-scalar and experiment it refers to.  $x$  indicates what shifting-scalar was used when shifting the input keypoints, and  $y$  indicates which of the three experiments from Section 5.2 the run belongs to. Each plot has at least one dot, which indicates the reduction of the learning-rate due to five consecutive epochs without beating the minimum validation loss.

By comparing the validation accuracies of the various models against the identity function we see, that all of the models, except for DeciWatch 1.3, do learn to somewhat denoise the input data. The simple 3-dimensional convolutional layer seems to be the architecure that generally delivers the greatest results, whereas DeciWatch is generally the architecure that delivers the worst results. Further, the two architectures that are based on bidirectional convolutional LSTMs have close to no difference in their performance, indicating that our raised concern about one of the architectures not being able to prioritize one LSTM-branch over the other is not as great as we hypothesized it to be.

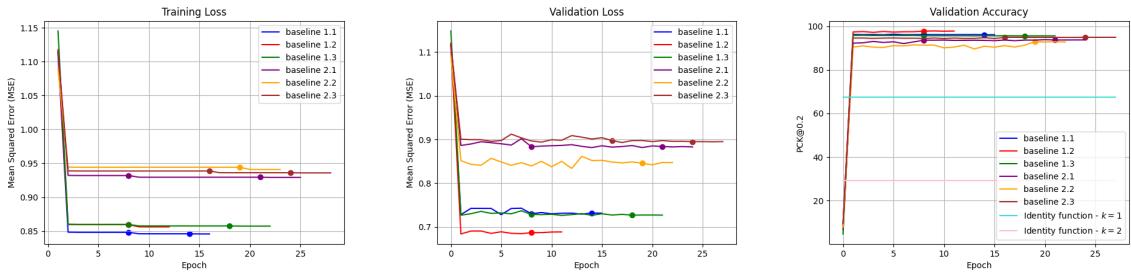

From the figure we can see, that generally the reduction of the learning rate has an effect on the training loss, as generally the training loss is immediately decreased after a reduction of the learning rate. However, the same cannot be said about the validation loss and accuracy, as these do not immediately decrease after the learning rate has been reduced. Often, the training even terminates before a second reduction of the learning rate takes place, indicating the missing effect of the learning rate reduction on the validation loss.

Further, we can clearly see the effects of the shifting-scalar on the training of the models, as all of the models perorms better on the dataset with a low shifting-scalar, than on their corresponding counterpart with a higher shifting-scalar. DeciWatch 1.3 and DeciWatch 2.3 do however seems to be struggling quite a bit, as the validation accuracies of these models are much lower than the other DeciWatch models with the same noise-scalar. However, we have to keep in mind here, that DeciWatch already only considers every fifth frame. This, combined with the fact that experiment 3 is only considering every other frame, makes these two models only consider every tenth frame, which of course makes the prediction very difficult.

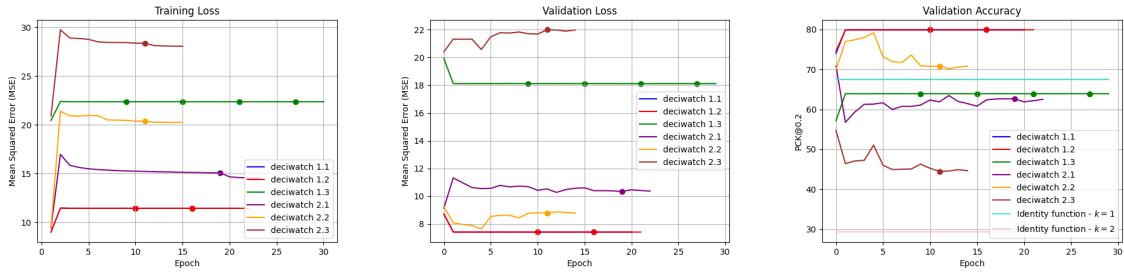

### 5.4 Test Results

We have in Table 3 and Table 4 illustrated the results of testing the epoch of each model that yielded the best validation PCK@0.2 accuracy.

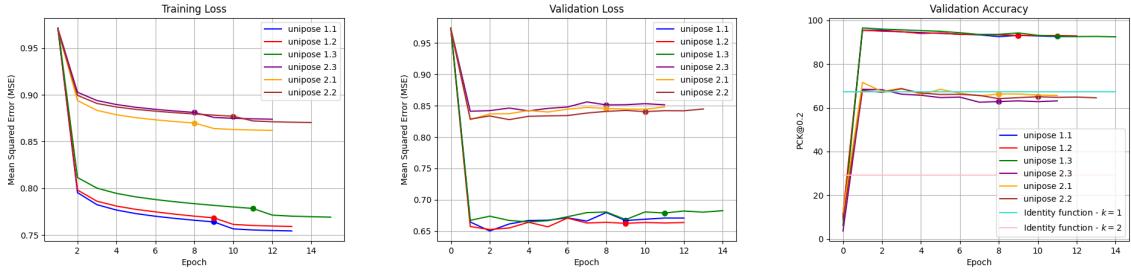

For shifting-scalar  $s = 1$  we see, that DeciWatch is the architecure that yields the best results

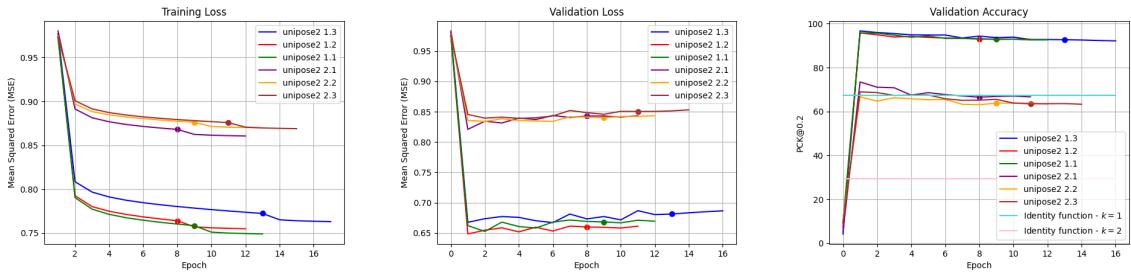

(a) Pretraining results of the 3-dimensional convolutional layer.

(b) Pretraining results of DeciWatch.

(c) Pretraining results of the bidirectional convolutional LSTM with summing.

(d) Pretraining results of the bidirectional convolutional LSTM with concatenation.

Table 4: Testing accuracies of the various developed models for shifting-scalar  $s = 2$ . All the accuracies are in percentage. \*: The mean maximum distance between the predicted keypoint and corresponding groundtruth keypoint for the prediction to count as being correct, using the units of the heatmap coordinates.

for PCK@0.05, however, for PCK@0.2 DeciWatch actually tends to be the worst performing model. Further, as stated in section ?? DeciWatch 1.3 does perform worse than the identity function when considering PCK@0.2, however, for both PCK@0.05 and PCK@0.1 DeciWatch 1.3 completely outperforms the identity function, hence why it actually does learn to denoise the data, unlike what we stated in section ?? where we just looked at the validation PCK@0.2. Generally, most of the predictions of DeciWatch that are considered correct, are actually very close to the groundtruth, however the predictions that are incorrect are pretty far away from their corresponding groundtruth location.

On the other hand, the simple 3-dimensional convolutional layer seems to be the architecture that generally performs the worst for PCK@0.05 and PCK@0.1, and actually the architecture that performs the best for PCK@0.2, except for run 1.3, where the two bidirectional convolutional LSTM based models actually outperforms it. Thus, the 3-dimensional convolutional layer is very good at inferring a rough estimate of the position of the keypoints, however, the exact position of these predictions are generally incorrect.

Generally, the bidirectional convolutional LSTMs yield some decent results, as the predictions of these models are always pretty far away from the worst-performing model for any of the three used accuracy metrics, and for PCK@0.1 they even seem to yield the best results of the four architectures. Similarly to the validation results, the test results do only indicate a minor performance differences between the two different types of bidirectional convolutional LSTMs in favor of the bidirectional convolutional LSTM with concatenation. Likewise, similarly to the validation results, the test results indicate a major effect of a low frame rate for DeciWatch.

If we compare the performances of the models on experiment 2 against their performances on experiment 1 we see, that the 3-dimensional convolutional layer performs much better on experiment 2 than it does on experiment 1. As the models of the first experiment have to learn both translation and scaling, where for experiment 2 the model only has to learn translation, we can clearly see how big of an impact the task of scaling the data has for this simple model. As for comparison, for the other architectures the performance difference between experiment 1 and 2 does not seem to be as great as it is for the 3-dimensional convolutional layer, indicating that these models are much better at scaling the input data. This is especially visible for DeciWatch, which has no performance differences between the two first experiments. However, this is due the architecture working on keypoint-coordinates instead of heatmaps, making it scaling invariant and thus making it, such that there are no differences between the two first experiments.

On the other hand, if we the results of experiment 3 against the results of experiment 1 we see, that both the 3-dimensional convolutional layer and DeciWatch perform worse on experiment 3 than it does on experiment 1. However, the the two architectures that are based on a bidirectional convolution LSTM actually continuously performs better in experiment 3 than they do in experiment 1, making us believe that the added context when decreasing the frame rate, actually helps these models.

The testing results of shifting-scalar  $s = 2$  generally follow the same pattern with some minor differences.

If we consider the results of PCK@0.2, the 3-dimensional convolutional layer is now the architecture that always yields the best results - and by a large margin, but is on the other hand completely outperformed by the other models when considering PCK@0.05. This indicates, that the architecture can still yield decent rough estimations of the keypoints when a lot of

noise is added, however, it does also indicate, that the exact position of these keypoints are very much effected by the level of noise. Further, its results in experiment 2 does not any longer outperform its results in experiment 1 when considering PCK@0.2, as it did in the case of shifting-scalar  $s = 1$ .

DeciWatch is now generally no longer the model that performs the best for when considering PCK@0.05, as it is now beaten by the architectures that are based on a bidirectional convolutional LSTM, except for experiment 2 where it completely outperforms the other models. Unlike in the case when using shifting-scalar  $s = 1$ , experiment 3 for DeciWatch now outperforms the identity function when considering PCK@0.2, indicating the effect of randomness of the results. Further, if we compare DeciWatch 2.1 and DeciWatch 2.2 against each other we see, that DeciWatch DeciWatch 2.2 continuously outperforms DeciWatch 2.1, although DeciWatch is scaling invariant and thus there should be no major performance difference between these two. Thus, this also shows how big of an impact randomness has on the results of DeciWatch.

Which architecture is the best at denoising the data depends on one's needs. If one just need a rough estimate of the position of the keypoints, then the 3-dimensional convolutional layer would be the optimal choice, as this model has the highest PCK@0.2-values. However, if one need the model which yields the most exact predictions, then one of the bidirectional convolutional LSTMs or DeciWatch would be the optimal choice.

Table 6: Keypoint-specific testing PCK@0.2-accuracies of the various models for shiting-scalar  $s = 2$ . All the accuracies are in percentage.

We have further in Table 5 and Table 6 illustrated the keypoint-specific testing PCK@0.2 of these models.

Looking at Table 5 we see, that the models with shifting-scalar  $s = 1$  generally perform the best on the more static keypoints such as the ears and shoulders, whereas they perform the worst on the keypoints that move more through out the video seuece, such as the ears wirsts and ankles. This of course makes sense, as it is harder to predict the location of moving key-points than it is for keypoints that do not move that much.

The models in Table 6 tells another story, as instead of performing the worst on the ankles and wrists, the elbows and knees are now the most difficult keypoints, and the ears, nose and ankles are now the least difficult keypoints. Why this happens is difficult to say. We suggest, that it might happen because the wrists and knees now are shifted so far, that they end up at the boundary of the heatmap, hence why they do not move as much as the knees and ankles.

## 5.5 Technical Details

All models were trained and evaluated on a shared GPU cluster using a 24GB NVIDIA Titan RTX and an Intel(R) Xeon(R) Gold 6248 CPU @ 2.50GHz. All models were implemented in Python version 3.9.9 using PyTorch 2.0.0. The 3-dimensional convolutional layer took about 60 minutes per epoch, DeciWatch about 86 minutes per epoch, the bidirectional convolutional LSTM with summing about 75 minutes per epoch, and the bidirectional convolutional LSTM with concatenation about 88 minutes per epoch.

## 6 Finetuning

As we now have finetuned our models, we need to finetune the models, such that they are specialized to yield optimal results on the ClimbAlong dataset. The following section describes the finetuning of these models. This includes the preprocessing of the data, the configuration details we use, as well as the obtained results.

In the finetuning stage we will be using the already developed pose-estimator to train our temporal-inclusive models. However, we will be freezing the pose-estimator, such that the weights of the model will not change during the training and we will thus only train our temporal-inclusive models. We do this for the following three reasons: (1) the training of the models will be quicker, as we just need to train the temporal-inclusive models and not the already developed pose-estimator, and (2) we get an greater understanding of the effects of our models when combined with the pose-estimator, as we can clearly see how big of a difference it makes by adding our temporal-inclusive models.

### 6.1 Data Preprocessing

For the ClimbAlong dataset we perform only minor preprocessing. First, the preprocessing of each video is done by having the already developed pose-estimator process the video, such that we have the output heatmaps of the pose-estimator, containing all of the pose-estimations of each video. Next, we preprocess the heatmaps by setting all negative values to 0 and normalizing each heatmap, such that each heatmap sums up to the fixed value  $c = 255$  that we used when preprocessing the BRACE and Penn Action datasets, essentially making the heatmaps more similar to the preprocessed heatmaps of BRACE and Penn Action. These heatmaps will then be used as the input for our models.

For the groundtruth heatmaps we create twenty five heatmaps of each frame, similarly to how we did it for the BRACE and Penn Action datasets, however, in this case we use the predicted bounding-box of the pose-estimator as our bounding-box. In cases where the groundtruth keypoint is placed outside of the bounding-box, we place the groundtruth keypoint at the closest border of the bounding-box.

### 6.2 Training Details

**Data Configuration** Generally, we follow a similar approach to how we did in the pretraining stage. We again use a window-size of  $k = 5$  frames, resulting in a total of 9,419 windows. Also here are we using  $c = 255$  as a representation of the ground truth placement of each keypoint. We also split the dataset into a non-overlapping and non-repeating training, validation and test set, consisting of 60%, 20% and 20% of the data, respectively. However, we note that one incorrect frame can have a huge impact on the evaluation results, as this frame is used five times during evaluation, and with the small dataset these five samples can have a huge impact. For that reason, for the validation and test set we make sure that no of the windows of the same set are overlapping.

**Experiments** As the finetuning dataset is so small, the fitting of the models is very quick, making us fit all of the 26 developed models from the pretraining stage. For each model we pick the epoch from the pretraining stage, that yielded the highest validation accuracy and use that for finetuning.

**Training Configuration** The optimization parameters are very similar to the ones from the pretraining stage. We again use the ADAM optimizer with a batch size of 16 and the MSE

loss-function. During training, we again keep track of the lowest reached validation loss of an epoch and use learning-rate reduction and early-stopping in a similar manner to how we did in the pretraining stage. However, unlike the pretraining stage, we here use a smaller initial learning rate of  $10^{-4}$ , as the weights only need to be fineadjusted, making us believe that greater learning rate would skew the weights too much.

### 6.3 Training and Validation Results

We have in Figure 15 illustrated the evaluation of the training loss, validation loss, and validation PCK@0.05 accuracy of the various models during the finetuning.

If we compare the models against the identity function we clearly see, how all models converge towards beating the identity function, indicating the positive effects of incorporating temporal information into the pose estimation of videos.

Further, most models tend to start off with a low validation accuracy, which could make one believe, that the pretraining has not had any effect. However, we can further see how the models tend to yield very good results after just one epoch of finetuning, making us believe that the pretraining has actually had an effect. One could argue, that a similar pattern occurred in the pretraining stage, which we would agree with. However, we have to remember that the pretraining stage contained many more samples, hence why the models were also trained on much more data in first epoch, and thus had a better likelihood of yielding good results after the first epoch, although they were not pretrained.

Generally, the shifting-scalar seems to only have a minor effect on the models during the finetuning, as all six runs of each model tend converge towards the same result. This however does not hold for DeciWatch, as the DeciWatch models with shifting-scalar  $s = 1$  seems to be having a lot of difficulty fitting compared to all of the other models, however, they do still yield some very accurate results.

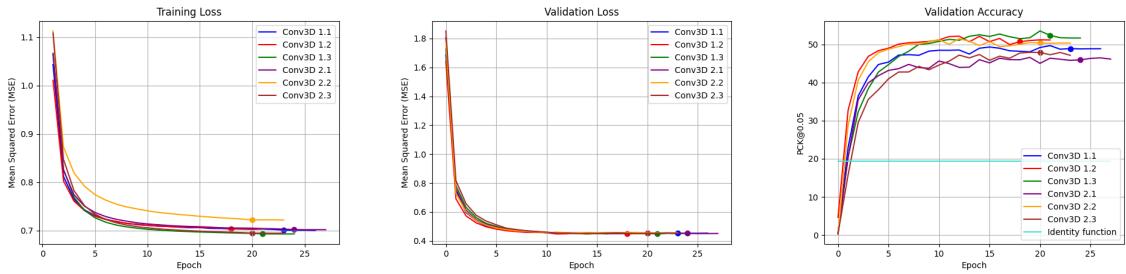

### 6.4 Test Results

We have in Table 7 and Table 8 illustrated the testing results of the epoch of each model that yielded the highest validation PCK@0.2 accuracy.

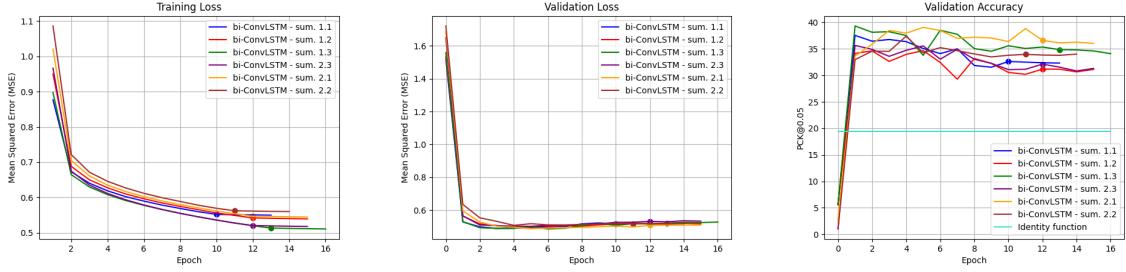

By comparing the two tables against each other we see, that the shifting-scalar tend to have a big effect on the results of DeciWatch. This is very similar to what we experienced in section

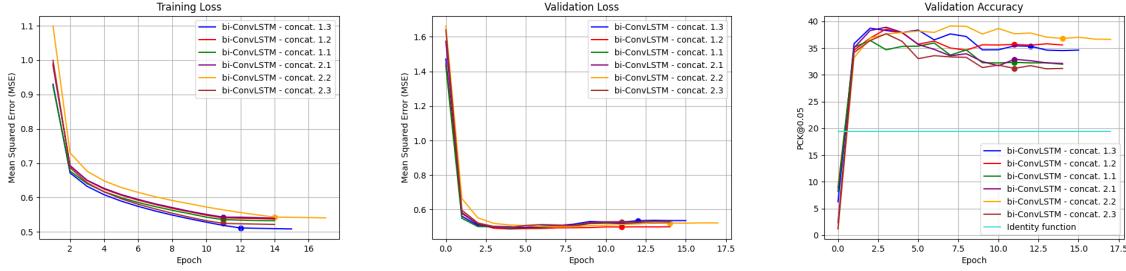

(a) Finetuning results of the 3-dimensional convolutional layer.

(b) Finetuning results of DeciWatch.

(c) Finetuning results of the bidirectional convolutional LSTM with summing.

(d) Finetuning results of the bidirectional convolutional LSTM with concatenation.

6.3, where we saw that the DeciWatch models with shifting-scalar  $s = 1$  had a lot of difficulty fitting. For the remaining models we do see a performance difference between the two shifting-scalars, however, the performance difference is not as big as it is for DeciWatch. Generally however, the models do perform best with the noise-scalar  $s = 1$ .

Similarly to the pretraining stage, we also see here how the 3-dimensional convolutional layer from experiment 2 performs better than the 3-dimensional convolutional layer from experiment 1, however, this performance difference is now smaller than it was in the pretraining stage.

Further, if we look at the DeciWatch-based models we see, that the models from experiment 3 yields the worst results out of the three, similar to how it did in the pretraining stage. For the three other models, the models from experiment 3 do not seem to have any consistent major impact on the final results.

Like in the pretraining stage, there does not seem to be any major performance differences between the two architectures that are based on the bidirectional convolutional LSTM, making us further believe that our concern about the missing opportunity of the model to prioritize a processing direction is not that important.

Accuracy metric	PCK@0.05			PCK@0.1			PCK@0.2

One might argue, that our way of splitting the evaluation set into a validation and test set carries some bias, as they are so similar and that we use the validation set to pick the models that we use for testing. To test whether this is true, we have in Table 9 and Table 10 tested the

Accuracy metric	PCK@0.05			PCK@0.1			PCK@0.2

same models on a video that have not been included in any of the other three sets. By looking at these two tables we clearly see, that none of the models perform worse than how they did in Table 7 and 8, indicating that no bias was introduced when we split the evaluation data into a validation and test set.

Table 11: Keypoint-specific testing PCK@0.2-accuracies of the various models for shiting-scalar  $k = 1$ . All the accuracies are in percentage.

We have in Table 11 and Table 12 illustrated the keypoint specific testing accuracies of the models.

By comparing these tables to the equivalent tables from section 5.3 we see, that most difficult keypoints are now the pinkies, the index finger and the thumbs, which were not a part of the pretraining dataset. One could argue, that there are two reasons for these keypoints being the most difficult keypoints. First off, they are the keypoints that tend to move the most, hence why they are the most difficult. Secondly, these keypoints were not a part of the pretraining dataset, so the model for these keypoints has only been fitted on the finetuning dataset. On the other hand, the heel and foot where neither a part of the pretrainng dataset and the models seem to yield decent results for these keypoints, hence why we believe that the suboptimal results for the fingers is simply due to them carrying a lot of movement.

## 6.5 Technical Details

All models were trained and evaluated using a 8GB NVIDIA GTX 1070 and an Intel Core i7-4790K @ 4.00GHz. All models were implemented in Python version 3.9.9 using PyTorch 2.0.0. The 3-dimensional convolutional layer took about 1.5 minutes per epoch, DeciWatch about 2 minutes per epoch, and the two bidirectional convolutional LSTMs took about 2.5 minutes per epoch each.

- Hvorfor performer mine modeller så meget dårligere på pretraining end på finetuning?
  - Vi kombinerer to meget forskellige datasæt
  - PA frame rates kan ødelægge det
  - Pretrain kan være sværre, fordi vi tiløjer (for meget) støj
  - Mask RCNN kommer allerede med ret gode resultater, så vi skal kun justerer end smule
  - BRACE groundtruth kan også indeholde noget noise da det kommer fra en model, som kan være svært at predicte.
- Val accs for deciwatch er faldende, men både train og val loss er også faldende.
- Deciwatch 2.2 performer meget bedre på single test video end på de resterende testing videos
- Conv3D er den bedste til denoise
- Conv3D er den bedste ifølge single video
- Hvilk model er den bedste?

## 7 Discussion

The following section discusses our approach, including the our choice of configuration of the models, the data and the training parameters, as well as suggests some future work.

### 7.1 Data Configuration

#### 7.1.1 Datasets

- Vanishing gradient for unipose - den fungerer bedre på range [0, 255] end på range [0, 1]
- Handling af data uden for pred bbox ved CA-data
- Valg af shifting-scalar:
  - Jeg kunne have approximeret den fra mask rcnn
  - Jeg kunne have gjort den afhængig af det enkelte led
- Pretrain: jeg shifter gt med op til 6 std, men jeg udglatter højest med 3, så jeg dækker egentlig ikke den rigtige placering af gt
- 

For the data we used three datasets. For the pretraining stage we used the BRACE dataset and the Penn Action dataset, whereas for the finetuning stage we used the ClimbAlong dataset. For our choice of pretraining datasets we see a couple of suboptimal choices.

BRACE and Penn Action can be very semantic different from each other. For instance, in the BRACE dataset the person in the video sequence is very often upside down and performs some very quick movements, whereas the people in the Penn Action dataset is usually in some more usual poses and do not make movements that are as quick as the ones from BRACE. We tried to fix this by only including video sequences from the Penn Action dataset that had more poses where the person was not just standing straight up, however, even by doing so, the two datasets are still semantically different. Further, the video sequences from the two datasets are often filmed from two very different camera angles, resulting in the same keypoints being placed at different locations. If the two datasets are very different this will have an effect on the fitting of the models.

We also see some problems in the pretraining datasets individually. For the BRACE dataset, it is clearly documented, that the video sequences is filmed using 30 frames per second. For Penn Action, on the other hand, a similar information is not stated anywhere and the video sequences comes as individual frames without the duration of the video sequences noted, hence why cannot either compute the frame rate of these video sequences. This could cause some problems, as a two windows of frames, one from each dataset, could span two different durations and thus capture two different duration of context. For the BRACE we also see an issue, as the dataset has not been fully manually annotated, but instead annotated using a pose estimator and only certain incorrectly predicted poses were manually annotated, where incorrectly predicted poses were detected by a machine learning model. However, if this machine learning model for detecting incorrectly predicted poses delivers suboptimal results, then the annotations would also be suboptimal and thus contain some noise, which is very difficult for our models to predict.

### 7.1.2 Data Preprocessing

For the preprocessing of the datasets, we split each video sequence into multiple windows of five frames. One could have argued, that we this was incorrect of us to do and that we instead should have used the whole video at once. However, we see a couple of problems with this. First off, this would require a lot of memory, as we have to store all of these frames at once. Secondly, for models like the 3-dimensional convolutional layer which has a parameter based on the length of the input sequence, this would be a problem, as the video sequences have different lengths and the only solution would thus be to either pad the shorter video sequences or trim the longer video sequences, such that all video sequences have the same length. Generally, we believe that our choice of cutting the video sequences into multiple windows was correct. However, one might argue, that these windows should consist of more than five frames, as this is way too little information for the models to learn the context of each frame, such that they accurately can perform temporal smoothing. However, we also disagree. We have clearly seen in section 5 and 6, how our models massively outperforms identity function, indicating that five frames is enough context for the models. Further, as stated by Artacho *Et al.*, the performance of the models plateaus after using more than five frames [2]. They did however use both different models and datasets than we did, so we could potentially have a different experience than what they did if we used more than five frames.

For the preprocessing of the pretraining dataset, the goal was to preprocess the data, such that it simulated the output of the already developed pose-estimator. This was done through multiple steps, where we used multiple values. For instance, we expanded the bounding-boxed created from the keypoints by 10% in each direction, we used a standard deviation in the range  $\{1, 1.5, 2, 2.5, 3\}$  for the Gaussian filter on the input data, and we shifted the input by sampling from a normal distribution with mean  $\mu_{in} = 1$  and standard deviation 3 or 6, depending on the experiment. These values were all some values that we came up with. We could instead have picked these values in a more sophisticated manner such that the data would be more similar to the ClimbAlong data. This could for instance have been done by approximating them from the ClimbAlong dataset. We could further have made this standard deviation keypoint-dependent, such that it would have modelled whether how much movement each keypoint makes. However, we do not believe this to be much beneficial, as (1) we generally already receive some great results which are difficult to beat, and (2) for the experiments where we increased the added noise, we did not see an improvement on of the keypoints that carry a lot of movement, for instance the pinky, hence why movement does not require a more shifted keypoint.

For the last part of the preprocessing of the pretraining dataset, we split the data into a training, validation and test set, consisting of 60%, 20% and 20% of the data respectively. This was done by making sure that none of the windows were repeated and that none of the windows were overlapping between the three datasets. By doing so we ensured that the evaluation did carried minimal bias, as the models had not seen any of the frames in the validation and test set during its training. However, different frames of the same video sequence could appear across the three sets, which could maybe carry some bias, as the same person would then appear in the three sets. However, we do not believe this to happen in our case, as the pretraining dataset does not include the actual frames but instead only include the annotations.

For the finetuning data we used the output of the already developed pose-estimator as the input to our models. Of course, by further fitting the already developed pose-estimator in connection with our temporal inclusive models we could have received some better results than what we did, however, we decided not to do so and instead to freeze the already developed pose-estimator, as this would decrease the training time of our models, as well as we can easily

see the difference it makes to incorporate the temporal information in the pose estimation, as this was the major goal of the project.

For the finetuning dataset we also used a window consisting of  $k = 5$  frames and a value of  $c = 255$  in the heatmaps as a representation the ground truth placement of the keypoints. We simply did this, as it was the most similar to how we did it in the pretraining stage and thus the model would have to learn less than in the case that we used another setting.

## 7.2 Model Configuration

- Model parametrer

## 7.3 Training Configuration

- Skulle have brugt en længere patience til early-stopping
- 
- Kør eksperimenter flere gange for at fjerne randomness i resultater.

## 7.4 Future Work

- Transformer uden skipping af frames
- Dataaugmentation til CA
- Træn uden PA
- Vision transformer
